Low-frequency Fourier analysis of speech rhythm

Sam Tilsen
Keith Johnson

Abstract

We present a new methodology for studying speech rhythm, based upon low-frequency Fourier analysis of the amplitude envelope of bandpass-filtered speech. Rather than quantifying rhythm with time-domain measurements of interval durations, we use frequency-domain representations to characterize speech rhythm with a metric based on a rhythm spectrum. In this paper we describe our method in detail, and using the Buckeye corpus, we illustrate and discuss approaches to characterizing rhythm with low-frequency spectral information.

1. Introduction

Most studies of speech rhythm use interval durations to describe temporal patterns. Defining an interval duration requires the selection of endpoints, which are moments in time. A variety of rationales exist for how to choose relevant moments, and these rationales depend upon what information in the acoustic signal is considered most appropriate for identifying rhythmic patterns. A guiding principle in the selection of moments is to define intervals that are psychologically important, i.e. subject to cognitive control or perceptually relevant.

One of the most prevalent uses of interval durations is found in cross-linguistic studies of speech rhythm, which have generally been concerned with the hypothesis that languages belong to distinct rhythmic classes of stress-timed, syllable-timed, and mora-timed languages (Pike 1945; Abercrombie 1967). This hypothesis holds that speakers of a given language organize their utterances so as to produce relatively isochronous intervals between either stressed-syllables, syllables, or morae. If true, evidence of such timing should be found in a tendency toward isochrony of intervals. In other words, the durations from the onset of one unit to the next should be less variable for timed intervals than for intervals not used to organize speech. For example, in a stress-timed language, interval durations between stressed syllables should be substantially less variable than those between syllables or morae. In a syllable-timed language, inter-syllable durations should be relatively less variable than inter-moraic and inter-stress interval durations. Consequently, the durations of inter-stress intervals in a stress-timed language should not be highly correlated with the number of syllables contained in those intervals; likewise, in a syllable-timed language the durations of syllables should not be highly correlated with the number of morae in the syllables.

Research into these predictions has failed to reveal a greater degree of syllable and stress-interval isochrony in syllable-timed and stress-timed languages, respectively. Bolinger (1965) and later on Dauer (1983) found that interstress interval durations in English were proportional to the number of syllables contained therein and varied according to their constituent syllable shapes. Furthermore, Roach (1982) found similar syllable durations in several languages that are purportedly stress-timed and several that are purportedly syllable-timed.

One reason that attempts to identify isochronies have not been successful may be, as Lehiste (1979) suggested, that isochrony is perceptual in nature. Perhaps a cyclic rhythm is
perceptually imposed on only vaguely isochronous productions. Hence relative isochrony would
to necessarily be observed in speech interval durations. Along these lines, the perceptual system
may compensate for rhythmic perturbations due to factors such as syllable shape or number of
syllables in a foot. Just as perceptual mechanisms correct for contextual variation in the signal
due to the overlap of articulations, so might rhythmic variation due to these factors be corrected,
leading to the perception of isochrony not present in the acoustic signal itself.

A different interpretation of the failure to identify rhythmic classes with interval
measures is that the choice of salient moments used in these studies did not define the intervals
most appropriate for uncovering patterns of isochrony. That is, the intervals between onsets of
syllables or onsets of stressed-syllables do not correspond to consciously controlled or
perceptually relevant durations, and thus do not reveal a cross-linguistic pattern that correlates
with perceived rhythmic differences between languages.

There are other reasonable possibilities for the choice of moments to define cognitively
important intervals. One is the beginning of a syllable vowel nucleus, another is the amplitude
peak associated with a syllable, yet another is the center of integrated amplitude (analogous to a
center of gravity). A more complicated but more cognitively-motivated construct is the “p-
center” of a syllable. This concept arose from finger tap alignment studies by Allen (1972,
1975), in which subjects tapped their index finger along with stressed syllables. Allen found that
subjects tapped their fingers somewhere close to vowel onsets, and he called the temporal
location of the finger tap the “production-center” of a syllable. The concept was then refined
using a dynamic rhythm setting task, in which the timing of a syllable relative to reference beats
is manipulated with a knob. These experiments have shown that a perceptually salient center of a
syllable also exists near the vowel onset (Morton, Marcus, & Frankish 1976), and that the exact
location of the center is influenced by the presence and duration of onset and coda clusters.

These findings have led a number of researchers to attempt to develop algorithms to
approximate p-centers from acoustic signals. Howell (1988) used the amplitude
envelope of a syllable to predict the location of its p-center. Pomino-Marschall (1989) used a
gammatone filterbank (which approximates auditory nerve responses) and a nonlinear function
of energy events defined by thresholds in syllable constituents; Scott (1993) used the energy in a
specific band of the spectrum, and Cummins and Port (1998) used a variation on this method
where the band was 700-1300 Hz—this frequency-band is useful in identifying energy associated
with vowels and filtering out energy associated with obstruents.

An alternative reason why convincing evidence for isochrony has not been found could
be that rhythmic differences between languages do not arise from isochrony whatsoever. As
Dauer (1987) has argued, there may be no way to choose consistent points in time to define
intervals that are relatively isochronous. In other words, the hypothesis that languages fall into
distinct rhythm classes, based upon which prosodic units tend to be isochronous, could just be
plain wrong. In that case, our impressions of cross-linguistic rhythmic differences could arise
from perceptual attention to a different sort of acoustic information.

One intriguing approach along these lines is to attribute perceived rhythmic differences to
phonological characteristics of languages. Dauer (1983) observed that stress-timed languages
tend to have more syllable types and heavier syllables, along with weight-sensitive stress;
additionally, stress-timed language have greater vowel reduction in weak syllables. However, not
all languages exhibit all of the characteristics prototypical of a particular class, and so Dauer
(1987) has argued that there is a continuum from stress-timed to syllable-timed languages.
To address these observations, Ramus et al. (1999) operationalized Dauer’s hypothesis using measurements of vowel and consonant durations in an utterance. Their rationale for this approach is attributed to Mehler et al. (1996), who proposed that infant speech perception relies primarily on vowels, partly because consonants tend to have less acoustic energy. Ramus et al. (1999) used three measures derived from interval durations: \%V, the proportion of the duration of a passage taken up by vowels, and \( \Delta C \) and \( \Delta V \), the standard deviations of the durations of consonantal and vocalic stretches in running speech. With these parameters they were able to distinguish syllable and stress-timed languages: stress-timed languages tend to have relatively high \( \Delta C \) and \( \Delta V \), and low \%V, reflecting the observation that vowels sometimes reduce and syllable shapes are more diverse in these languages. In contrast, syllable-timed languages tend to have relatively low \( \Delta C \) and high \%V, reflecting a more limited set of syllables and less reduction. Japanese has an even lower \( \Delta C \) and \%V—perhaps indicating a third moraic-timing cluster.

Despite the success of this approach, the question remains as to whether the phonological properties of languages are what give rise to the percept of rhythm, or are merely epiphenomena of something else perceptible in the speech signal. This “something else” may not even be detectable with interval durations. Before we describe a methodology that is designed to overcome the limitations of interval-duration approaches, a few more issues should be pointed out here.

There may be a fundamental problem with the idea that syllable-timing or stress-timing is a property of a language, rather than of a particular utterance. If it can be shown that some utterances in a given language are more syllable-timed and others are more stress-timed, then perhaps the appropriateness of the cross-linguistic classification needs further reexamination. To show this, what is needed is a way of characterizing rhythm that does not rely on statistics of interval durations.

An even deeper problem with the stress/syllable/mora-timing trichotomy is that these so-called prosodic units may not be primitives with respect to speech rhythm. It is conceivable that the groups of speech gestures affiliated with a mora or a syllable or a stressed syllable (i.e. “head of a foot”) may sometimes pattern abnormally and adopt timescales characteristic of the other units. For example, (phonologically/lexically) “unstressed” syllables may sometimes act more like stressed syllables, which in turn might sometimes pattern like morae. That is, rhythmic patterns might be dissociable from the prosodic units that are traditionally used to structure speech into hierarchical representations.

2. Method

2.1 Low-frequency spectral analysis

To understand how our method differs from interval duration methods, let’s begin by considering all of the information about the speech signal that interval duration measurements ignore. Such measures represent the interval between two points in time with a single number, its duration. This effectively eliminates from the numeric representation of the signal all details about its amplitude envelope. From a naïve perspective, this seems like an egregious omission of detail, yet this dissociation of interval duration from the contents of an interval is so common that it is almost never explicitly noted in methodological appraisals.
The reason that such neglect is so widespread may be related to the very basic metaphors that structure the most popular linguistic theories. Consider a CVCV foot like [sasa], in which the intersyllabic interval (i.e. the duration between syllable onsets) is very clearly defined. Assume that the measurement of such an interval involves negligible error (approx. < 10ms). Our theoretical construct of the SYLLABLE, i.e. $\sigma$, encourages us to think of this period of time as a container. By metaphoric extension, this container can be empty (or at least its contents irrelevant), in which case the most pertinent information about the container is its size—the duration of the syllable. The prevalence of this conceptual metaphor, along with the ease with which such durations can be measured, encourages us to ignore the contents of the container. The same metaphor structures our understanding of interstress intervals, i.e. feet, which are understood to contain syllable containers.

The approach in this paper is to give much less attention to where intervals begin and end, and more attention to the acoustic contents of those intervals. We do this by analyzing the frequency spectrum of the slowly undulating amplitude envelope of speech. Consider now the segmented speech waveform in Fig. 1, where the citation form, phonetic transcription, and deletions are shown in tiers below. This utterance is about 2.3 s in duration, and contains 14 syllables.

Fig. 1. Acoustic waveform and segmentation of a 2.3 s utterance from the VIC corpus.

One of the first things to notice about the speech signal is that in the long term, its integrated amplitude tends to zero (assuming a decent microphone), since the negative and positive pressure variations for voiced speech cancel each other out on small timescales. It is the magnitude (absolute value) of those variations that we are really interested in, because the magnitude varies more slowly and does not cancel itself out when integrated on small or large timescales.
Fig. 2 below shows the signal from Fig. 1 in panel (a) and its magnitude in panel (c). Panel (b) shows the same speech signal after it has been filtered using a 1st-order Butterworth filter with a passband of 700-1300 Hz, which is the same filter that Cummins & Port (1998) used to detect p-centers. The frequency-response of this filter decreases gradually from the cutoffs, so a fair amount of energy outside of the band remains in the signal after the filtering. The bandpass-filtered signal reflects primarily vocalic energy, because it filters out glottal energy and most of the noise occurring in obstruents, especially sibilant energy. However, it also responds better to low and back vowels than high-front vowels with low F1 and high F2; hence the bandpass-filtered signal does not represent the energy of all vowels equally. Panel (d) shows the magnitude of the bandpass-filtered signal.

Fig. 2. Unfiltered (a) and bandpass-filtered (b) acoustic signals, along with corresponding magnitudes, (c) and (d).

To eliminate the rapid amplitude fluctuations of vocal fold vibration, we lowpass filter using a 4th-order Butterworth filter with a 10 Hz cutoff. The resulting signal is extremely redundant, so we downsample from 16000 Hz to 80 Hz to get rid of some—but not all—of the redundancy. This corresponds to an increase in sampling period from 0.0000625 s to 0.0125 s. Downsampling eliminates a fair amount of information, but plenty has been retained. Fig. 3(a) shows the downsampled lowpass-filtered magnitude (superimposed over the magnitude of the bandpass-filtered waveform) after a 45 ms correction has been made for the phase-delays of the filters (this correction is the sum of the mean phase delays of the bandpass filter in the 700 to 1300 Hz range and the lowpass filter in the 0 to 10 Hz range). Fig. 3(b) shows this same magnitude over the original waveform, after the magnitude has been windowed (using a Tukey window \( r = 0.1 \)) and the mean has been subtracted.
The low-pass filtered magnitude (or “processed magnitude”) represents slow changes in the amplitude envelope of vocalic energy in the original waveform. The last step before the spectral analysis is performed is to pad the processed magnitude with zeros and normalize so that its variance is unity, as represented in equation (1).

\[
\frac{1}{N} \sum_{t=1}^{N} (x_t - \bar{x})^2 = \sigma^2 = 1
\]

Next we apply a Fourier transform (FT) to derive a frequency domain representation from the time-domain amplitude envelope signal. The FT preserves all of the same information that was contained in the processed magnitude, in the sense that the FT can be inverted to reconstruct the original signal. The Fourier transform is based upon the Fourier series (eq. 2), which can be used to approximate any real function.
for $\omega_j = 2\pi j/N$ and $t = 1...N$, the finite Fourier series is:

(2) 

$$x_t = a_0 + \sum_{j=1}^{N/2-1} (a_j \cos(\omega_j t) + b_j \sin(\omega_j t)) + a_{N/2} \cos(\pi t)$$

where 

$$a_0 = \overline{x}$$

and for $j = 1...N/2 - 1$

$$a_j = \frac{1}{N} \sum_{t=1}^{N} x_t \cos(\omega_j t)$$

$$b_j = \frac{1}{N} \sum_{t=1}^{N} x_t \sin(\omega_j t)$$

Re-expressing (eq. 2) in polar form (eq. 3) gives us a direct representation the phase and amplitude of sinusoidal components of the signal.

for $j \neq N/2$, the $j^{th}$ harmonic in polar form:

(3) 

$$a_j \cos(\omega_j t) + b_j \sin(\omega_j t) = R_j \cos(\omega_j t + \phi_j)$$

where 

$$R_j = \sqrt{a_j^2 + b_j^2}$$

$$\phi_j = \tan^{-1}\left(\frac{-b_j}{a_j}\right)$$

One of the nice aspects of the information expressed by the FT is that it still bears a meaningful relation to our intuitive understanding of “rhythm”; arguably, it is even more relevant to measuring rhythm than interval durations are. One way to think about why the FT representation of the signal provides a good view of rhythm is to see it as the wisdom of the crowd. Each otherwise insignificant datapoint within all of the intervals in the entire signal contributes to the representation of the signal—as if polling a bunch of people has given us a more accurate idea of the overall inclinations across the population. Indeed, in profound contrast to the interval-based approaches, here no intervals whatsoever are defined, only frequency components with associated phases and amplitudes.

Note that the normalization to unit variance imposed upon the time series (eq. 1) is retained in the sum of Fourier amplitudes (eq. 4), a fact which follows from Parseval’s Theorem (c.f. Chatfield 1975; Jenkins 1968; Anderson 1971). The Fourier Transform thus partitions the variance of the time series into components of differing amplitude at each of the Fourier analysis frequencies.
The Fourier coefficients still contain far more information than we can use. For starters, we will discard information about the phase of each frequency component—not because this information is entirely irrelevant to rhythmic analysis, but because we assume that the phases of high-energy periodicities nearby in the frequency spectrum cluster together, and hence there is a fair degree of redundancy between the phase and amplitude information on local frequency-scales. The raw power spectrum, or periodogram, (eq. 5; Fig. 4) indicates how much each frequency component contributes to the waveform.

\[
\sigma^2 = 1 = 2 \sum_{j=1}^{N/2-1} R_j^2 + R_{N/2}^2
\]

The last step in this process is to smooth the power spectrum with bandwidth \(L\), as shown by the red line in Fig. 4. Smoothing is accomplished using a moving average filter (eq. 6), and it is common to treat the spectrum as symmetric about 0 for this purpose (cf. Chatfield 1975, who describes the use of a Daniell filter for this purpose). The redundancy added by smoothing makes hypothesis testing easier, because the confidence intervals associated with smoothed spectra are narrower, owing to the fact that each smoothed amplitude value represents the average of values from a number of nearby frequencies. However, because of the nonlinear relation between frequency and period, this form of smoothing introduces greater spectral blurring for periodicities corresponding to longer intervals than for ones corresponding to shorter intervals—hence in some circumstances we will want to analyze the raw (unsmoothed) power spectra.

\[
X(\omega_j) = \frac{N}{2\pi} \left( \frac{R_j^2}{2} \right)
\]

Fig. 4. Raw (blue) and smoothed (red) spectrum. \(L = 31\) points. \(N = 2048\).
It is instructive to compare the smoothed spectrum in Fig. 4 to the processed magnitude and waveform from Fig. 3(b), repeated in Fig. 5 below. The most dominant peak in the spectrum has a frequency of about 3.7 Hz, corresponding to a period of about 270 ms. Looking at just the seven highest peaks in the magnitude in Fig. 5, one can see that a number of them are separated by around 250-300 ms (3-4 Hz), which accords well with the spectral representation.

There are also smaller peaks at 6 Hz (167 ms), 2.2 Hz (450 ms), and 0.5 Hz (2 s). The presence of high-amplitude components at these frequencies implies that peaks in the magnitude signal should recur approximately at intervals corresponding to those frequencies. Fig. 5 additionally shows all of the intervals between all peaks in the signal.

\[
X_{\omega_m}(\omega_j) = \frac{1}{L} \sum_{j=m}^{j+m} X(\omega_j)
\]

where

\[
m = (L - 1)/2
\]
Fig. 6 shows a histogram of all the peak-to-peak intervals from Fig. 5. The highest concentration of durations is in the bins flanking 200 ms. There are also high concentrations in bins flanking 500 ms. These 200 and 500 ms interval duration concentrations are approximately what the spectrum predicts (i.e. 6-3.7 Hz ≈ 167-270 ms and 2.2 Hz ≈ 450 ms), but these correspondences are inexact because the interval duration approach does not take into account the amplitude of the peaks which define each interval.

Note that the duration of the signal defines a fundamental frequency—or, to avoid confusion, “minimal frequency”—which is the lowest frequency fitting within the signal period. Any peaks in the spectrum which occur below twice the minimal frequency of the signal, do not in any sense indicate the presence of a periodicity within the signal. Rather, these peaks indicate a global imbalance in the distribution of energy in the signal, which can be manifested as substantially louder speech in one part of the utterance, a lengthened filler, or various other forms of disfluency. In the example above, the signal period is 2.2 s, and so the minimal frequency is 0.45 Hz and spectral peaks below 0.9 Hz do not represent true periodicities.

2.2 VIC corpus chunks

For the current investigation, we are using speech from the Buckeye corpus (Pitt, Johnson, Hume, Kiesling, & Raymond 2005), which is a collection of approximately 300,000 words of conversational speech between interviewers and 40 native central Ohio English speakers. Three factors—age of speaker (over 40, under 40), gender of speaker, and gender of interviewer—were balanced across the interviews. The corpus was phonetically transcribed and segmented by transcribers trained to use acoustic and spectrographic information, following a number of conventions to ensure consistency.

To analyze the corpus, we first extract “chunks” of speech with no interruption or non-speech vocalization. In addition, the extraction procedure can separate chunks by all silences, or
a silence duration parameter can be set so that only silences greater than some duration cause chunks to be separated. There are a number of basic variables that are associated with each chunk, these include the duration of the chunk, the number of syllables (here considered equivalent to the number of vowels and syllabic consonants), the number of non-syllabic consonants, and the rate of syllables per second. Additionally, because the corpus is phonetically-segmented, it is possible to infer when segmental deletions and alternations have occurred, by comparing the citation form of a word to its phonetic transcription. Figs. 7-9 show the distributions of some of the basic chunk variables for raw chunks extracted from the corpus. Note that the mean rate of syllables per second is approximately 5 σ/s. Table 1 shows correlations between these basic chunk variables. As one might expect, the number of syllables in a chunk and its duration are highly correlated, and there is also a fair degree of correlation between rate and syllable count. Furthermore, there is some correlation between rate and chunk duration, which reflects the observation that very short chunks are likely to consist entirely of hesitations, fillers, or pitch-accented one-word utterances.

![Duration Histogram](image1.png)

![Syllables Histogram](image2.png)

Not unexpectedly, the duration of a chunk tends to have a substantial effect on its spectral profile. Fig. 10 shows average raw power spectra and average smoothed power spectra for 1-2 s, 2-3 s, 3-5 s, and 5-7 s chunks. At low frequencies (below 1 Hz), a sizeable relation between chunk duration and spectral amplitude is apparent. This is due to the fact that longer chunks allow for lower frequency periodicities. At higher frequencies (above 2 Hz), the 2-3, 3-5, and 5-7 s chunk spectra pattern together, tending to have less energy than the 1-2 s chunks. This asymmetry may be due to changes in speech rate being more common in longer stretches of speech, or may arise because the Fourier transform partitions a greater proportion of variability into lower frequencies for longer chunks. Note that due to its smaller sample size, the average power spectrum of 5-7 s chunks is fairly noisy.
Because expected spectral profile is influenced by chunk duration, relations between chunk spectra and other variables cannot be directly evaluated without first taking measures to reduce the impact of chunk duration on those other variables. A simple way of accomplishing this is to analyze a subset of chunks that fall within a predetermined range of durations. In general, the choice of subset duration range depends upon the timescales of the rhythms being investigated. If one is interested in foot or syllable timescales, shorter chunk durations are more appropriate, because over longer durations speech rate and rhythm are more variable. Hence in the range of frequencies corresponding to foot and syllable timescales (approximately 1.5-6 Hz), spectra derived from longer chunks are less informative. If one is interested in phrasal timescales, longer chunk durations are more appropriate.

Rather than leaving unanalyzed the raw chunks whose durations are greater than the upper bound of a given duration range, we divide these chunks into subchunks. For illustrative purposes in this paper, we chose a chunk duration range of $\tau = (\tau_1, \tau_2) = (2, 3)$ s, because we suspect that this range is useful for studying syllable- and foot-timed rhythms. The number of subchunks that can be obtained from a raw chunk of duration $T > \tau_2$ seconds is $\text{floor}(T - \lambda)$, where $\lambda$ represents a target overlap between successive chunks. If $\lambda = 1$, two chunks can be obtained from a 3.75 s chunk, and three from a 4.12 s chunk, etc. The target duration of each chunk is $(\tau_1 + \tau_2)/2$, but we apply a random perturbation (from -0.5 to 0.5 s) to the target subchunk endpoint in order to make the overall distribution of durations more uniform. The actual resized-chunk durations are determined by the segment boundaries nearest to the target startpoint and randomly perturbed target endpoint. Figs. 11-13 below show the distribution of...
chunk durations, syllable counts, and syllable rates in the 2-3 s subset. The average chunk rate is about 5.5 σ/s, and the average number of syllables per chunk is between 12 and 13.

![Chunk Durations](image1)

![Chunk Syllables](image2)

Fig. 12. 2-3 s chunk syllable count frequency

![Chunk rates](image3)

Fig. 13. 2-3 s chunk rates

Correlations between basic chunk variables for the entire subset are repeated in Table 2, and those for the 2-3 s chunk subset are shown in Table 3. Notably, the correlation between duration and syllables is diminished in the subset, while the syllable count-rate correlation is greatly increased. Most importantly, the duration-rate correlation is reduced, making the duration of a chunk a less significant factor on the chunk rate. This allows for more reasonable comparison of slow-speech and fast-speech spectra.

3. Analysis

In this section, we present example chunks and spectra from the 2-3 s subset, provide descriptive statistics characterizing spectral variance in these chunks, and then discuss techniques for analyzing the low-frequency spectral information. We do not analyze data for the sake of making an argument here; rather, we illustrate a variety of issues that arise in the analysis of spectral information.

3.1 Examples

Figs. 14-18 below show examples of 2-3 s chunks that are highly periodic relative to the mean spectrum for 2-3 s chunks. The top panel in each of the following figures shows the waveform and processed magnitude, along with citation, transcription, and deletions. (In the original electronic copy of this paper, sound files are linked to the figure so the reader can listen to the examples). The middle panel shows the smoothed spectrum against the mean and 2.5 standard deviation region for the entire subset of 2-3 s chunks. The bottom panel shows the average amplitude across each of nine frequency bands, against the mean and 2.5 standard deviation interval for the subset in each band. These frequency bands can be seen as a further reduction of dimensionality in the description of the chunk spectrum, but no principled reason choosing these specific ranges has been determined. Figs. 14-17 show chunks with high periodicity in the 1-2 Hz, 2-3 Hz, 3-4 Hz, and 4-5 Hz ranges, respectively. Fig. 18 shows a chunk without a periodicity exceeding 1 standard deviation in any of the energy bands.

Fig. 14. High-amplitude periodicity in the 1-2 Hz band.

Fig. 16. High-amplitude periodicity in the 3-4 Hz band.
Fig. 17. High-amplitude periodicity in the 4-5 Hz band.

Fig. 18. No periodicity exceeding 1 standard deviation in any energy band.
3.2 Spectral variability

One of the first questions that arises in considering spectral data is how often high-amplitude periodicities occur in a chunk. The flip-side of that question is how often no high-amplitude periodicities occur at all. This question can be answered by counting the number of chunks with spectral peaks exceeding a power threshold. Table 4 shows the percentages of chunks with an spectral amplitude value exceeding 30 amplitude units, which can be seen to be indicative of a rhythmic component in the examples shown above. These data indicate that the presence of high-amplitude periodicity in speech is more prevalent than one might have thought: approximately 16.5% of chunks have a >1 Hz high-energy periodicity.

</tbody>
</table>

We note here that the frequency bands chosen for the above presentation are the same as the ones shown in the examples in the preceding section. The ranges of these bands are mostly arbitrary, and in future analyses a priori principles for choosing particular band ranges may be discovered. The band ranges chosen above give equal import to periodicities in the 1-2 Hz range and the 8-9 Hz range—this is probably not the most sensible choice, since the spectral peaks of chunks are not uniformly distributed throughout this range.

A nice way to visualize the variability of chunk spectra is to examine the distributions of frequency peaks and their amplitudes. For each amplitude envelope spectrum, we can locate the highest peak—perhaps within a certain range of frequencies—and plot that value against its amplitude. We define the peak as the highest local maximum of the spectrum which has lower amplitude neighbors, rather than as the global maximum of the spectrum, because some smoothed spectra have their global maximum located at 0 Hz (which is an artifact of the spectral smoothing procedure, not a direct current component of the signal). Fig. 19 (a), shows a 2-dimensional Gaussian kernel density plot of peak frequencies and their corresponding amplitudes from all the 2-3 s chunks. Fig. 19 (b) shows a similar density plot, where only peaks representing true periodicities (i.e. peaks above twice the minimal frequency of a chunk) were chosen. Fig. 19 (b) indicates that the dominant periodicity of a 2-3 s chunk in the VIC corpus tends to fall in the range of 1.5-3.5 Hz. Further, there appear to be two subclusters, one centered around approximately 1.5 Hz (666 ms) and another around 2.5 Hz (400 ms).
Fig. 19. Frequency peak-amplitude densities (a,b).

Note that the Gaussian kernel density bandwidths and the ranges in which the densities are calculated and plotted affect how the density plots appear. For all the density figures in this report, we have used a frequency kernel bandwidth of 0.2 Hz, which means that each point in the density plot represents the Gaussian integration of peaks within +/- 0.2 Hz. We used an amplitude range from the 0.1 percentile to the 99.9 percentile of amplitude values, and an amplitude kernel bandwidth of 5% of the amplitude range. We have also included 90%, 50%, and 25% density contours (white lines) in each plot.

A second point to be made about the procedure for obtaining peak frequency-amplitude densities is that the peak-detection process is inherently biased to select peaks at low frequencies over ones at higher frequencies. This is simply because the low-frequency rhythms in chunks correspond to stressed syllables and accents, and hence have greater energy in the processed magnitude. These low-frequency rhythms then receive more of the variability in the partitioning effected by the Fourier transform, and thus the low-frequency peaks tend to be higher in amplitude. This makes higher frequency peaks less likely to be selected by the peak-picking algorithm. One way to remove this bias is to normalize each spectrum according to the average spectrum of some set of data. In the current examples, we normalize by the mean and standard deviation spectra of the entire 2-3 s chunk subset. The normalization procedure is analogous to calculating a z-score for each point in the spectrum, and it removes the low-frequency bias in the spectrum. What is left is an indication of where in the spectrum the most outlying peaks—relative to the entire dataset—are found, as well as how outlying those peaks are.

Fig. 20 below shows frequency-amplitude densities for 2-3 s chunks, using normalized spectra. Panels (a) and (b) show normalized peak densities when peaks are drawn from the full range of the spectrum and from frequencies above twice the fundamental, respectively. Panels (c) and (d) show the corresponding z-scores. Note that regions of apparently high-density in the upper end of the amplitude plots do not correspond to high-density regions in the z-score plots; this disparity occurs because the amplitude values are more compressed in the upper end of the spectrum but the kernel density estimation procedure treats frequency and amplitude as linear. We therefore recommend using z-score plots to interpret normalized peak densities. Note that the
same problem applies to non-normalized density plots, but on account of spectral bias, these tend not to have as many peaks in the upper end of the spectrum.

Fig. 20. Frequency peak-amplitude densities obtained from normalized spectra. (a) and (c) show peaks in the 0-9 Hz range, (b) and (d) peaks above twice the minimal frequency of the chunk. (a) and (b) show amplitudes, (c) and (d) the z-scores used detect the highest peak.

What Fig. 20 (d) indicates is that when smoothed spectra are normalized to account for spectral bias, the majority of outlying peaks tend to be located between 1 and 3 Hz. Yet peaks in the range of 3 to 5 Hz become much more noticeable with the normalized peak-detection algorithm. Peaks in the 4-5 Hz range are especially intriguing if one interprets this range to be associated with syllable-timing. Assuming English is stress-timed, one would expect—and indeed this is borne out in the figures above—that peaks in the 2-3 Hz range would dominate the others, because this range presumably contains the average interstress interval in English. Yet the presence of chunks in which a 4 Hz periodicity is strong suggests that on occasion, English rhythm patterns more like that of a syllable-timed language.

The presence of faster rhythms in English suggests a dual-mode hypothesis: speakers can make use of both stress-timing and syllable-timing, but for any given language, one pattern will
be more dominant. To rigorously test this hypothesis, one would need to identify a number of English utterances which exhibit high periodicity at syllable-associated frequencies and show that these differ in certain ways from utterances without high-periodicity at those frequencies. One potential difference should be a relative diminution of the cues that are normally associated with stress, e.g. greater duration of stressed syllables, more peripheral vowel qualities, greater intensities, and larger pitch excursions.

While all of the peak densities shown above were derived from smoothed power spectra, it is equally practical to take peaks from raw power spectra. Fig. 21 (a) and (b) show raw and smoothed peak-amplitude densities. Note the difference in scales. Panels (c) and (d) show the corresponding normalized densities. Because the spectral blurring introduced by smoothing is more problematic for lower frequencies, the use of raw spectra for peak density may be more appropriate for analysis of the low end of the spectrum. Note also that the raw spectra do not suffer from edge effects at 0 Hz, because the raw spectra always have 0 amplitude at 0 Hz (owing to the subtraction of the mean from the processed magnitude signal).

Fig. 21. Peak-density plots from raw spectra (a) and smoothed spectra (b), along with corresponding normalized peak-density plots (c) and (d).
The peak detection algorithm used to produce the above figures takes only the highest true peak from each spectrum and ignores any other peaks. The algorithm thereby discards potentially useful information about less energetic rhythms in a chunk. To rectify this we can select an arbitrary number of peaks from each spectrum and include all of them in the density plot. In practice, it does not make much sense to select more than the 3 or 4 highest peaks from each spectrum, since lower-amplitude peaks are not very representative of signal periodicities. Fig. 22 shows smoothed spectrum peak-densities and their normalized peak-density counterparts, where increasing numbers of peaks have been drawn from each spectrum. One can see that as more peaks are taken, a greater number of peaks in the 5-8 Hz range are selected, but relatively more are also taken from the 1 Hz range, which leads to obfuscation of the 2-3 Hz mode visible in (a). The normalized peak-amplitude densities confirm this: as more peaks are taken from each spectrum, the density in higher frequencies is diminished relative to the density in the lower end of the spectrum.
Fig. 22. Multiple-peak density plots (left) and corresponding z-score density plots (right).
Peak-amplitude density plots also offer a useful way of uncovering differences between datasets. Consider subsets of 2-3 s chunks in which speech rate (syllables per second) is greater than and less than the mean speech rate. Fig. 23 (a) shows the density difference between these fast- and slow-speech subsets, where two peaks have been drawn from each spectrum. To compute the difference, both density matrices are normalized to sum to the same value, and then one is subtracted from the other. In this case, the blue region is where the proportion of peaks taken from slow speech is substantially greater than the proportion taken from fast speech. The red regions are where the proportion of fast-speech peaks is greater than the proportion of slow-speech peaks. As one might expect, slow speech exhibits a predominance of peaks at the lower end of the spectrum, while faster speech has lower amplitude low-frequency peaks, and of course high-frequency peaks. The normalized peak-amplitude density difference (b) shows the same pattern, except that there is no concentration of fast speech density at the low end of the spectrum; this implies that the fast-speech low-frequency peaks visible in (a) were selected due to spectral bias.

![Fig. 23. Non-normalized peak-amplitude (a) and normalized peak-amplitude (b) density difference plots (2 peaks per spectrum) showing differences between fast and slow speech.](image)

One promising use of density difference plots is to uncover rhythmic differences between speech with and without deletion. Fig. 24 shows peak-density and normalized peak-density difference plots between subsets of data consisting of chunks that did or did not have consonant or vowel deletions, where rate has been controlled by excluding chunks beyond 1 standard deviation from the mean rate of the entire dataset. These figures show that consonant deletion is associated with rhythms around 2 Hz, but rhythms around 2.5 Hz are associated with consonantal preservation. In contrast, vowel deletions are strongly associated with 2.5-3 Hz rhythms, while vowel preservation is associated with 1 Hz and 5-6 Hz rhythms.
Fig. 24. Peak-amplitude (left) and normalized peak-amplitude (right) density difference plots (2 peaks per spectrum) showing differences between spectra of chunks with and without consonant (top row) and vowel (bottom row) deletions.

One interpretation of these results is that 1 Hz and 5-6 Hz rhythms are associated with disfluency/phrasal-accents and syllable-timing, respectively. Phrasal accents and disfluency tend to slow speech, making vowel deletion less likely. Syllable-timing involves a periodicity that governs both stressed and unstressed syllables; this periodicity makes the vocalic gestures associated with unstressed syllables more stable and less prone to deletion. Further, we might divide metrical foot-timing into slow and fast varieties: slow (1.75-2.5 Hz) foot-timing preserves vocalic gestures but provokes consonantal deletion, while fast (2.5-3 Hz) foot-timing makes unstressed vowels prone to deletion but preserves consonants. Intriguingly, consonants are preserved in fast foot-timing, but prone to deletion in 4 Hz rhythms. Explaining why these patterns are observed requires a theory of rhythmic-gestural interaction that remains to be developed; but, in general terms, such a theory may involve dynamic coupling between metrical and gestural systems.
4. Conclusion and Future Directions

This report has presented a method for the quantitative analysis of rhythm that does not utilize interval durations, but rather, uses spectral analysis of lowpass-filtered magnitude signals. We believe this technique has the potential to augment studies of speech rhythm in a variety of ways. It offers an new approach to cross-linguistic rhythmic typology that involves statistical comparisons between large corpora of conversational speech. It can offer insights into rhythmic styles and characterizations of fluency from sociolinguistic and clinical perspectives. It may also shed light on relations between speech rhythm and intergestural timing, providing a deeper understanding of variation in conversational speech.
